

Titles

Chilling dominates tree budburst in controlled climate experiments, but not in the great outdoors

Chilling outweighs photoperiod and forcing cues in temperate trees in experiments, but not in natural systems

Abstract

Decades of research on woody species highlight how three major cues shape spring phenological events (e.g., budburst and leafout): forcing (warm temperatures, generally occurring in the late winter and early spring), daylength (photoperiod) and chilling (cool temperatures, generally occurring in the fall and late winter). How pervasive these cues are and whether some species are effectively governed by only one or two cues is a critical area of climate change biology research, as it would shape how complex responses to warming will be. Here we use a global meta-analysis of all published growth chamber studies to test for the relative effects of these three major cues across XX species. We find they almost all show these cues, making climate change responses complex.

Text so far...

For decades, plant phenology has been one of the most reported and consistent biological imprints of climate change (IPCC, 2014), with many temperate plants leafing and flowering earlier with rising temperatures (cites). Understanding such shifts is important as phenology shapes a suite of ecosystem services, including pollination and carbon sequestration, and scales up to impact projections of climate change itself.

As research interest in phenology has progressed, critical discrepancies and uncertainties in our understanding have emerged. Though responses to warming are consistent on average (Wolkovich et al., 2012), they show high variation across species and sites (cites). Furthermore, long-term observational studies provide increasing evidence that sensitivities of phenology to temperature are weakening in recent decades (Yu et al., 2010). In Europe, recent work from some of the most well-studied tree species shows declining responses to temperature, suggesting that the long-term trend towards ever-earlier springs may be stalling (Fu et al., 2015). The authors, and others, suggest that responses to other environmental cues underlie these declining temperature sensitivities.

Fundamental research in phenology outlines three major cues known to shape spring phenology (Chaine, 2000): chilling (cool temperatures, generally occurring in the fall and late winter), forcing (warm temperatures, generally occurring in the late winter and early spring), and daylength (photoperiod). Research suggests these cues drive spring phenology for many temperate woody species (CITES), but there is strong debate over how prevalent these cues are across species (KornerBasler etc.) and which cues dominate (CITES). Given the declining response to temperature observed in long-term observational studies (Fu et al., 2015), a number of papers have tried to tease out evidence of unfulfilled chilling or daylength cues in recent years (CITES), but such work must overcome the fundamental challenge that all three major cues are often strongly correlated in nature. During the transition from winter to spring at many temperate latitudes, air temperatures increase (i.e., forcing increases) at the same time that daylength is increasing; likewise, winters with low amounts of chilling are often correlated with warmer springs, and thus higher forcing. Identifying which of these cue(s) most strongly affect spring phenology is critical for forecasting future phenological changes. For example, if forcing is the dominant cue (as many studies to date have assumed, CITE), then we can expect additional spring advancement

as temperatures continue to warm. However, if unfulfilled chilling limits budburst, then we may see delays in spring phenology with additional global warming, which will reduce chilling in many areas (?).

In contrast to observational studies, controlled environment experiments can break correlations between chilling, forcing, and photoperiod to reveal mechanistic links between environmental conditions and budburst phenology. These experiments—most often conducted in growth chambers or similar systems to control temperature and light—have been conducted for decades as a major method to understand the fundamental drivers of spring phenology. To date, controlled environment experiments have identified contrasting effects of the three major budburst cues. Some studies have proposed that photoperiod is likely to constrain species responses to climatic warming (Basler and Körner, 2012; Caffarra et al., 2011b; Caffarra and Donnelly, 2011), whereas others report that photoperiod is not a strong cue for most species (Zohner et al., 2016; Laube et al., 2014).

Here, we leverage nearly 40 years of controlled environment studies to understand how chilling, forcing, and photoperiod contribute to budburst timing in woody species. Using a meta-analytic approach we first reviewed XX papers from controlled environment studies, then extracted data from any papers that met [XX conditions] yielding data from 74 studies across 39 years and 223 species (reference map of studies). This database includes only studies for which we could identify forcing, photoperiod, and chilling treatments quantitatively. (Chilling was rarely reported and for studies missing this information, we estimated it ourselves when possible using climate data for the experiment cite. See Supplemental Materials). We used a Bayesian hierarchical model to estimate the effects of chilling, forcing, and photoperiod. This model partially pools for a robust overall effect, and for robust effects for species with lots of data (*Fagsyl*, *Betpen*) but pools towards the mean for species with fewer data (See Supplemental Materials- mention species complex).

We find that budburst phenology is determined by chilling, forcing, and photoperiod—all three cues are important and all three advance budburst. Chilling was the strongest cue, advancing budburst at a rate of XX days per XX chill portions. Chilling effects were largely consistent across species, though two species showed the opposite pattern (delaying budburst with higher chilling, *Tilia codata*, *Salix* complex). Forcing advanced budburst at a rate of X days per degree of warming, overall, consistent with what previous experiments (CITES), and observational studies (CITES) have found. There are differences in the ways that chilling and forcing are experimentally applied. Forcing is generally applied as a straightforward manipulation of increasing temperatures in experimental chambers. In some cases chilling is manipulated directly, as well, by altering the temperature in chambers or the duration of time spent in a chamber with chilling conditions (e.g., cite experimental chilling papers). In many studies, however, chilling is manipulated via the Weinberger method (citation), in which dormant twigs are collected at sequential dates during the winter, with the assumption that twigs left outside longer have experienced more chilling. The challenge with this method is that photoperiod and other factors may have also changed during this time. Most studies do not experimentally apply chilling by manipulating duration or temperature of chilling, nor do most estimate the chilling imposed in their experiment. We therefore calculated the chilling imposed by most studies, as it would otherwise have been impossible to provide estimates with only experimental chilling (reference lizzie’s supp heat maps). In addition, we find that the way that chilling is measured alters the estimated effect of chilling on budburst (cite supplemental table comparing estimates with both units). We therefore present models fit two the OSPREE dataset with chilling summarized using two different units: Utah (citation) and Chill portions (citaiton). Though chilling and

photoperiod estimates differ slightly quantitatively (i.e., they are slightly lower using chill portions compared to Utah) the effects of chilling and other cues remain qualitatively the consistent across the two chilling units.

We expect climate change to continue to have dramatic effects on spring phenology, because the two temperature-derived cues (chilling and forcing) both strongly affect budburst,

1. Photoperiod
 - (a) Photoperiod ... very consistent across species, suggesting all species do cue to it (ref Zohner, Caffara, Flynn ??)
 - (b) The magnitude of photoperiod effects varies with latitude, with lower source latitudes generally having earlier budburst. Say provenance (population).
2. We did not estimate interactions. Why? .. Add in node to process based models here.
 - (a) Very few studies actually design experiments to test for interactions, so there is little to build on
 - (b) The few studies that do interactions often use the weinberger method, which seems a little weird based on our results.
 - (c) They're hard for a couple reasons: need more reps, and photothermoperiodicity.
 - (d) And! We cannot fully disentangle forcing vs. chilling conditions. (Chuine et al. 2016 GCB).
 - (e) Our results average over interactive effects.
3. One paragraph: A simple interpretation of our model – especially its chilling and photo effects – predicts declining sensitivities in long-term data with climate change. This is because even though forcing increases, chilling is expected to decrease and photoperiods should get shorter – both predicting delays, and thus an overall muted effect of temperature-only. (Ref exp conditions forecasting figure.) But how do experimental temperature and photoperiod compare to predicted ones in nature? (Ref experimental conditions forecasting figure)
4. But how do the conditions overlap with natural conditions? (PEP + experimental data figures)
 - (a) Forcing isn't bad
 - (b) Experimental chilling is generally lower than field chilling
 - (c) Photoperiod differences are very big in experiments
 - (d) Declining sensitivities in PEP data (need to check)
5. Forecasting with these semi-real data, however, do not predict a decline in sensitivity given the moderate amounts of warming already seen, instead they suggest general advance of budburst until extremely high warming (ref. forecasting figure with PEP-based data)
 - (a) Chilling often increases with small amounts of warming in some sites
 - (b) Even if warming only happens in the winter, it takes a lot of warming to see a delay due to decreased chilling

- (c) At higher warming do see a leveling off or delay due to decreased chilling at some sites
 - (d) Depends a lot on local climate... We also find that patterns of advancement with warming vary considerably depending on the current/background climate (e.g. how much advancement will continue with warming depends on how much chilling is currently experienced and whether that will increase or decrease with warming.)
 - (e) (Compare advances in our models to PEP725 data?)
 - (f) Photoperiod effects are minimal, even for *Fagus*
6. So why is PEP725 showing declining sensitivities?
- (a) Our results suggest few sites with delays before 3-4 degrees warming (CHECK)... and Germany has warmed X amount
 - (b) Speeding up a biological process given sampling time resolution could lead to declining estimates of sensitivities, even if unchanged
 - (c) Say something about what to do about this and how to figure out if this is the issue or it's cues.
7. Our results suggest most or all studied species are responsive to these three cues
- (a) Our results are only for one region, but highlight how critical accurate forecasts of shifts in forcing and chilling will be at local scales
 - (b) To do this, we desperately need to better understand chilling (dormancy release) so that we can predict it in the future (maybe say need better models for chilling across species).
 - (c) Alongside this, we need more fundamental understanding of interactive cues, which requires larger studies across diverse species. Our results include these complexities but a finer understanding is needed in locations where cues do not change in concert.
 - (d) These complexities are unlikely to alter our fundamental predictions of an increasing advance for many temperate trees in the future, even those with strong chilling or forcing cues (ref Gauzere) [Alt: An improved understanding of interactive cues, however, is unlikely to alter our fundamental predictions of an increasing advance for many temperate trees in the future, even those with strong chilling or forcing cues (ref Gauzere), unless cues are changing very asynchronously.]

Figures

Figure 1: Budburst model estimates

1. μ plots
2. μ forecasting figures: spring x winter warming – PEP climate range and experimental climate range
3. Species forecasting with PEP data: *Betula*, *Fagus* ... need to think on which ones to use (x sites x species focus etc). ... Maybe show photoperiod one?
4. PEP data figure with environmental conditions: as in Cat's figure + OSPREE data + maybe forecasting (at 2C or such?)

Supplemental figures/tables:

1. Map of study locations, shading or symbol coding for number of cues (Lizzie)
2. Map of species forecasting to justify sites
3. Tables, yes.

4. Heat maps for the main data, including by actual study design and by calculated chilling (our calculations)
5. Photoperiod x latitude effects figure
6. Equation of our model
