Abstract

Climate change has shifted plant phenology globally 4-6 days per °C on average, with some species shifting much more. Such shifts have been some of the most reported and predictable biological impacts of rising temperatures. Yet as climate change has marched on, phenological shifts have appeared more muted over recent decades—failing to match simple predictions of an advancing spring with continued warming. The main hypothesis for these changing trends is that other cues of spring phenology—long-documented in lab environments—are playing a greater role in natural environments due to climate change. Here we argue that accurately linking shifts observed in long-term data to underlying phenological cues requires a greater integration of long-term data with results of lab experiments conducted in controlled environments. We highlight how seven decades of research in controlled environments can improve predictions for when, where and how the interactive effects of other cues will impact simple linear predictions. At the same time a new generation of controlled environment experiments could rapidly improve our predictive capacity for woody plant phenology in coming decades.

Keywords: phenology, climate change, spring warming, chilling, forcing, daylength, photoperiod, non-linear responses, leafout, budburst

1 Main text

Shifts in spring plant phenology are one of the reported and most predictable changes with climate change. Decades of research have documented advancing budburst, leafout and flowering across systems with climate change (Delpierre *et al.*, 2009; Yu *et al.*, 2010; Ellwood *et al.*, 2013; Jochner *et al.*, 2013; Hereford *et al.*, 2017), especially in temperate systems where long-term records highlight how humans have altered the timing of spring (Schwartz, 1997; Menzel *et al.*, 2003, 2006). Recently, however, these advances have appeared to slow (Fu *et al.*, 2015) or even reverse in some places (Yu *et al.*, 2010)—failing to match simple predictions of an advancing spring with continued warming (Ellwood *et al.*, 2013). The main hypothesis for this failure is that spring warming—which most observational studies focus on—is no longer the only environmental cue that matters to predicting responses to warming (Chuine *et al.*, 2016; Gauzere *et al.*, 2019).

Despite the strong focus of spring phenology research on spring temperatures, increasing evidence suggests a more complicated underlying physiology for most plant species (e.g., Zohner *et al.*, 2016; Gauzere *et al.*, 2019; Ettinger *et al.*, 2020). For many species three major cues underlie spring phenology: forcing (warm temperatures, generally occurring in the late winter and early spring), chilling (cool temperatures, generally occurring in the fall and winter), and photoperiod (daylength).

Together, forcing, chilling and photoperiod may produce non-linear responses that many current methods do not predict, but observational studies appear to have seen recently (Fu *et al.*, 2015). Predicting these non-linearities is a common goal in plant phenology research today (Güsewell *et al.*, 2017; Martinez-Luscher *et al.*, 2017; Gauzere *et al.*, 2019; Chen *et al.*, 2019; Keenan *et al.*, 2020), but has been slowed by data gaps and the underlying complexity of spring phenology.

The first step towards improved phenological predictions is robust measurements of chilling, forcing and photoperiod cues. Recently, efforts have focused on estimating these cues from long-term observational data (Luedeling *et al.*, 2009, 2013). Yet observational studies may struggle to robustly estimate any of the three major cues due to two types of statistical issues. First, in most observational data these cues are correlated: forcing increases alongside longer photoperiods (Elmendorf & Ettinger, 2020), and chilling and photoperiod cues both yield similar predictions (i.e., both cues predict later spring phenology with warming). Approaches that attempt to disentangle some of these correlations, such as leveraging trends across elevation or latitude, may run afoul of other correlations (Tansey *et al.*, 2017). Second, most observational studies focus on linear models of each cue, often without interactions between cues (Visser & Holleman, 2001; Polgar *et al.*, 2014; Asse *et al.*, 2018).

In contrast to the limitations of observational studies, one method is designed to measure the complexity of cues: controlled environment (e.g., growth chamber) studies (Nagano *et al.*, 2012; Satake *et al.*, 2013). Such studies have been conducted for over 70 years and are specifically designed to understand non-linearities both in individual cues and produced by interactions between cues. In contrast to observational studies, controlled environment studies can manipulate

all three cues, extend to other cues that may be important in some species or biomes (e.g., humidity, drought conditions, light spectra), and can tease out interactions between cues by experimentally decoupling them.

Despite the prevalence of controlled environment studies on spring phenological cues, they have rarely been reviewed. Perhaps more surprisingly, they are often poorly integrated into the current phenological literature on climate change. This includes in debates where they are critical, such as about the importance of photoperiod (e.g., Fu *et al.*, 2015; Richardson *et al.*, 2018).

Here we review how the long-term literature on controlled environment studies can be integrated into current phenological research on climate change more fully. We begin by outlining how the three major phenological cues—forcing, chilling and photoperiod—can produce non-linearities and how they will shift in coming decades with anthropogenic climate change. We then review controlled environment studies to understand how much of the cue-space (i.e., the possible range of each cue and interactions across cues) has been studied and how experimental treatments compare to shifts in cues caused by climate change. Based on this, we discuss how controlled environment studies can be best designed to build more robust predictions.

Given our aim to improve understanding of current trends and forecasts we focus on early vegetative phases (budburst and leafout), which are critical to plant growth and thus to models of carbon uptake and storage, and which have shifted most with climate change (Cleland *et al.*, 2007; IPCC, 2014). We touch on other areas of research, which have been important to our understanding of the cues underlying phenology. In particular, research has been especially strong in model systems (e.g., *Arabidopsis*, *Populus*) and crops (Cesaraccio *et al.*, 2004)—with the exact phenophase of interest varying (more focus on germination and flowering in *Arabidopsis*, and more on leafout and budset in *Populus*). Given our focus on budburst and leafout, our review concentrates on woody species phenology. Most of our conclusions and suggested approaches, however, could be adapted to non-woody species and other phenophases with similar underlying interactive cues.

1.1 How do phenological cues produce non-linear responses?

Forcing, chilling and photoperiod cues together determine budburst each year for woody species in many temperate species (e.g., Chuine & Regniere, 2017; Ettinger *et al.*, 2020). Forcing and chilling cues are generally understood to be accumulation processes, where plants must integrate chilling and forcing experienced over time to meet a threshold value at which they can budburst, leafout or flower (Chuine, 2000). In contrast, photoperiod is generally not considered an integral cue, but one evaluated daily (Singh *et al.*, 2017). In practice, these two types of processes are often abstracted into the effects of average experienced values (mean temperature or daylength), either over some window in long-term data (e.g., Wolkovich *et al.*, 2012a; Fu *et al.*, 2015), or through controlled environments that hold temperatures and light regimes more constant (e.g., Worrall & Mergen, 1967; Heide, 1993a,b; Skuterud & Dietrichson, 1994).

Controlled environment studies show two major ways these cues can produce non-linear responses—each cue alone, or through interactions between cues (Fig. 1). Each cue alone may produce a non-linear phenological response when examined across a sufficiently wide range of values (Fig. 1B). Cues may be linear in the mid-range of values, while extremely high or low values of some cues may produce threshold responses (Gauzere *et al.*, 2017). For example, at very low photoperiod (short days) plants often will budburst erratically (Heide, 1993a; Partanen *et al.*, 1998; Singh *et al.*, 2017; Rinne *et al.*, 2018), while at sufficiently long photoperiods maximum growth may occur, meaning photoperiods longer than some threshold will have no additional effect on budburst timing (e.g., Major, 1980). Similarly, extremely cool or very hot temperatures may limit forcing as plant developmental processes slow (Parent & Tardieu, 2012). Such extreme values of cues, however, are likely less common in most natural environmental regimes than interactions between cues that can produce non-linearities.

More commonly, the interaction of cues can produce non-linearities. For example, multiple studies now show that the threshold of forcing needed for budburst depends on the sum of chilling over the fall and winter and also by the photoperiod experienced in the spring (e.g., Zohner & Renner, 2014; Flynn & Wolkovich, 2018). Higher forcing is generally needed given lower chilling (Fig. 2) and shorter photoperiods (Basler & Körner, 2014; Fu *et al.*, 2019). This yields a classic subadditive interaction of forcing x chilling and forcing x photoperiod, where high values of both cues together produce a more muted response than would be expected from studies examining either cue alone. This interaction of cues produces a non-linearity in environments where values of cues are correlated over time or space—for example, chilling declines that are correlated with greater forcing (Fig. 1A)—and may be critical to accurate forecasts with climate change (Fig. 1C-F).

1.2 How will chilling, forcing and photoperiod shift with climate change?

Translating when or if these non-linearities may be triggered by warming first requires understanding how climate change alters each of the three cues. All three cues are expected to shift with climate change, though the shifts will vary substantially across space and time (Burrows *et al.*, 2011). Most notably to date, warming increases the forcing plants experience each day, with more rapid shifts—and thus also greater shifts—at higher elevations and in the arctic (IPCC, 2014). Daily temperature minima (generally night-time temperatures) generally have warmed, and will continue to warm, more than maxima (though this effect varies spatially, Alexander *et al.*, 2006), making efforts to understand whether plants accumulate temperatures differently in the night or day critical (Prasad *et al.*, 2008; Shen *et al.*, 2018).

Warming across seasons is also variable (Alexander *et al.*, 2006), meaning warming’s impact on forcing (generally accumulating in the late winter and spring) may not be equivalent to impacts on chilling (generally accumulating in the late fall through winter). Warming should translate into important shifts in chilling, which long-term observational studies have repeatedly suggested may already be occurring (Fu *et al.*, 2015; Piao *et al.*, 2017). Our poor understanding of chilling, however, makes current and predicted shifts in chilling complicated (Chuine *et al.*, 2016).

Research to date suggests chilling only accumulates in a certain range of temperatures with low (e.g., $<0^{\circ}\text{C}$) temperatures generally not contributing to chilling accumulations and higher temperatures (e.g., $>12^{\circ}\text{C}$) potentially decreasing previously accumulated chilling (see Fig. 3 and Richardson, 1974; Fishman *et al.*, 1987). Long-term studies generally focus on the warmer part of this chilling accumulation curve, suggesting that chilling should decrease with warming (Fu *et al.*, 2015; Piao *et al.*, 2017; Gauzere *et al.*, 2019). However, considering the cooler part of this curve, chilling could also increase with warming (Guy, 2014), which we would predict to yield much earlier budburst, potentially far earlier than last frost dates.

Unfortunately, these predictions for chilling are based on models developed almost solely for agricultural crops (but see Harrington & Gould, 2015), especially stone fruits, and have rarely been robustly adapted to forest trees. While the development of classic models of chilling for peaches and related fruit trees benefited from data on these species being planted far outside their range into regions with extremely low or potentially no chilling, equivalent data on forest trees is almost never available (Dennis, 2003). Thus chilling models to date generally use limited observational and experimental data from forest trees to try to re-parametrize the basic stone fruit models (Chuine, 2000; Chuine *et al.*, 2016). This limited understanding of the physiology and process of chilling in trees, makes any current observations of shifts in ‘chilling’—and all forecasts with warming—uncertain. Thus, we believe it is important to consider both increases and decreases of chilling as potential outcomes of warming (Fig. 3).

Shifts in chilling and forcing with warming have been studied far more than shifts in photoperiod (but see Saikkonen *et al.*, 2012; Way & Montgomery, 2015). While an environment’s photoperiod does not shift with climate change, the relevant photoperiod a plant experiences at critical physiological points may change dramatically with warming. In particular, increases in chilling and/or forcing, which could alone produce much earlier budburst, may be offset by short photoperiods that delay budburst (Gauzere *et al.*, 2019). Similarly, long photoperiods can lead to budburst sooner than predicted by solely low chilling or forcing conditions (Nienstaedt, 1966; Myking & Heide, 1995; Partanen *et al.*, 1998). Thus, changes in chilling and/or forcing correspond to changes in the relevant photoperiod experienced with climate change.

These shifts—in forcing, chilling and photoperiod experienced near the time of an event—can produce non-linearities when they push a single cue across a critical threshold or inflection point (see threshold response in Fig. 1B). For example, if some species have a critical photoperiod for budburst and warming means forcing cues are met before the critical threshold, then we would expect incomplete or highly delayed budburst (Singh *et al.*, 2017; Rinne *et al.*, 2018). Alternatively, the threshold could be crossed in the opposite direction. For example, if pre-climate change conditions generally caused budburst to occur at the extreme values of some cues, but now climate change has pushed budburst into values where responses are more linear. This is often the mechanism suggested for declining responses to warming in some temperate trees (Fu *et al.*, 2015; Piao *et al.*, 2017; Gauzere *et al.*, 2019), specifically that plants previously accumulated sufficient chilling for a minimal effect of chilling—making forcing the dominant

cue—whereas warming has now reduced chilling such that more forcing is needed for budburst (producing an overall muted effect when estimated as change in days per °C, see Fu *et al.*, 2015, for one example). As this example highlights, however, changes in a single cue are unlikely to occur without additional effects on other cues—complicating how well we can understand them in long-term data without robust understanding of the exact cue requirements from experimental studies.

We expect most non-linearities from climate change will come from the effects of interactive cues, either where changes in one cue trigger shifts in another cue or due to covarying shifts in cues (Fig. 1). While simple linear interactions between cues may not alone produce non-linearities (see ‘no interaction’ lines in Fig. 1C-F), they quickly become non-linear when changes occur together—for example if increased forcing also occurs in step with shorter photoperiods experienced at the time of an event (Fig. 1C-F). Predicting these non-linearities, however, requires a refined understanding of the interaction between cues and whether there are critical inflection points that may be crossed with continued warming. These complexities highlight how difficult predictions may be without careful efforts to tease out how each cue works alone and interactively.

1.3 Forecasting non-linear responses

Controlled environment studies can help predict non-linear responses by allowing researchers to examine the effects of one cue with the others held constant, and examine interactive effects, given the appropriate study design. Such experiments may be especially useful for forecasting if they contain enough variation in treatments to capture precisely where non-linearities occur, and are designed across a range of levels relevant to current versus future conditions (Shen *et al.*, 2015). Indeed, one of the major advantages of experiments is that they allow treatments outside of the historical range of a species’ or region’s climate—an option long-term observational data cannot provide.

We reviewed controlled environment studies over the last seven decades to understand the range of treatments already available, and how they compare to current and future conditions. We note that these studies were rarely conducted for climate change research, and most often done for fundamental science or other areas of applied science (e.g., horticulture or forestry). Yet they are some of the best available data for how plants respond to the environment and thus a critical resource for climate change research today.

How studies and their experimental treatments vary globally

Controlled environment studies have been conducted across 226 woody species across the globe, with the majority of papers reporting research occurring in Europe (54 of 84 papers; and 93 of 136 studies across papers; a study is a unique experiment within a paper), followed by North America (22 papers and 32 studies, Fig. S1). Most studies manipulate one cue though studies of two or three cues have occurred in almost every decade (Fig. S2). Across study designs, chilling was the most commonly studied cue (69% manipulated chilling of 117 studies that manipulated forcing, chilling and/or photoperiod), followed by forcing and photoperiod (43% manipulated

forcing; 40% manipulated photoperiod).

The levels of cues (e.g., 8 or 10 hours of photoperiod) varied across latitude with a general trend toward examining more extreme values at higher latitudes (see Fig. S3). These shifts across space appear related to differences in extremes across latitudes (higher latitudes experience colder temperatures and longer photoperiods, and see similar shifts in their controlled environment study designs), but introduce a bias in results as any comparisons of studies from lower and higher latitudes are also comparing a different range of cues.

How studies manipulate cues

Studies can be broadly categorized as manipulating one, two or (rarely) three cues at once. Single cue studies were the most common (65 studies), with most manipulating chilling (41 studies), followed by 14 manipulating photoperiod and 10 manipulating forcing. Of the studies manipulating chilling 14 followed the design generally attributed to Weinberger *et al.* (1950) where tissue (e.g., cuttings of adult dormant trees) are taken progressively across the fall and/or winter seasons then exposed to controlled environment conditions. These studies often equate tissue removed later from the field as having received more chilling and thus often treat ‘time of cutting’ as interchangeable with ‘chilling,’ though forcing and photoperiod conditions also change. While valuable for defining potential non-linearities in one cue, single cue studies prevent understanding interactions among cues or comparisons of which cues dominate phenological responses—challenges that studies of multiple cues can overcome.

Of the studies manipulating at least one cue, roughly a third additionally manipulated another cue (37% or 43 studies). Study designs most often examined the interaction of cues (that is, whether the effect of one cue depends on the level of the other cue: 39 studies designed experiments to test this, while 4 studies did not), with the studies almost evenly split across all possible two-way interactions (14 studies tested for photoperiod x chilling, followed by 13 studies tested for forcing x chilling, followed by 12 studies tested for photoperiod x forcing).

Studies examining three cues directly were rare: we identified only three studies examining all three cues at once. Two of these were on *Picea abies* (Worrall & Mergen, 1967; Sogaard *et al.*, 2008), and the other on *Betula pendula* (Skuterud & Dietrichson, 1994). A slightly larger set of studies (5 studies from 4 papers) examined three cues indirectly—manipulating photoperiod and forcing in controlled environments but equating chilling with sequential removal of tissue from the field—for 11 species (Schnabel & Wample, 1987; Heide, 1993a; Partanen *et al.*, 1998; Basler & Körner, 2014).

The paucity of studies examining multiple cues limits our fundamental understanding of each cue, as well as how—when combined—they will determine future budburst with continued warming. Because the cues are all known to be interactive, estimates of any one cue are influenced by the level of each other cue. Knowing the level of each other cue is difficult both because they are often not reported (see ‘NA’ in Fig. 4), and also because of our limited understanding of dormancy, which divides chilling and forcing (Chuine *et al.*, 2016). Authors may use the

terms ‘chilling’ and ‘forcing’ for their treatments, but they rarely have physiological evidence that these are the actual conditions plants experience.

How relevant are treatments to current and future conditions?

The utility of controlled environment studies to forecasting also depends on how relevant treatments are to current and future conditions. Estimating such relevance is difficult as it depends on a species’ geographical range and projections considered. However, a simple analysis of two well studied species, *Fagus sylvatica* and *Betula pendula*, suggests experiments have generally bracketed the range of projected temperatures (Fig. 5). Projected changes in maximum temperatures generally fit within the range of temperature differences conducted within forcing treatments in experiments, and similarly matched differences in minimum temperatures in chilling treatments. As noted above, however, there is a limited number of chilling studies that directly manipulate chilling temperature. Indeed, we found no studies with multiple chill temperatures tested for *Fagus sylvatica*, even though it is one of the most well-studied species (Fig. 5C).

Experimental treatments were generally larger than expected shifts due to climate change. This makes sense from an experimental-statistical perspective: if the goal of an experiment is to identify if a cue is present then larger treatment differences should yield larger effect sizes and thus higher statistical power. But such large shifts may be risky to extrapolate to smaller shifts due to warming. Further, experimental studies vary from natural settings in myriad ways. Different studies have ameliorated some of these differences. For example, most studies (34 of the 48 that manipulated forcing) have constant day/night temperatures, but many vary day and night temperatures (26 studies; 12 of those studies also include constant forcing) with nights generally being cooler, while some have introduced ramped temperature through the day and across an experiment’s length (e.g., Basler & Körner, 2012; Laube *et al.*, 2014). Such ramped conditions are generally introduced across all treatments in experiments and thus provide little insight on how much such experimental artifacts matter (but see Erwin & Heins, 1995). This means extrapolating from controlled environment studies should be done with care, and highlights a need for future experiments specifically designed to improve climate change forecasting.

1.4 Paths forward

We argue that controlled environment experiments will be critical for accurate predictions of phenology given future warming. How accurate such predictions are will depend on the design of future experiments, breakthroughs in our physiological understanding of the major cues, and how well these two areas can be integrated with long-term data to improve models.

Improving controlled environment studies

We expect the most useful future experiments will be designed to improve phenological models. In particular, experiments designed to identify threshold effects and optimal temperatures/photoperiods, and non-linearities from interactive cues may be most useful (Iler *et al.*, 2013). Identifying threshold effects and optimal temperatures or photoperiods generally requires many different levels of a single cue, which can make such experiments difficult to cross with other cues. Yet, understanding if findings are consistent across varying levels of other cues

should be a follow-up step to confirm that findings can be applied across levels of other cues. Studies manipulating more than one cue also test for non-linearities due to interactive cues, as long as they are fully-crossed (i.e., every combination of levels is present in treatments). Such experiments can quickly require a large number of controlled environments, but provide critical information for models and to connect to long-term findings. As growing experimental results support that all cues are dependent on the level of other cues (Stearns & Olson, 1958; Flynn & Wolkovich, 2018) and long-term data hint at multiple cues (Fu *et al.*, 2015), we believe this should be a major research aim.

Controlled environment studies may also be more readily applied to forecasting by exploring more realistic conditions. While identifying thresholds, optima and non-linearities may involve considering informative extremes in levels of cues, most changes in cues due to climate change are and will be on a (relatively) smaller scale (Fig. 5). Thus, when designing studies to contribute to improved forecasting of a particular species, experimentalists should examine cues within the current and projected future species’ range. In most species distribution models, species are expected to remain in the same climatic conditions, suggesting there may be minimal changes—assuming such models of species distribution are accurate and that species track perfectly (Elith & Leathwick, 2009). Most evidence, however, suggests species will lag in their spatial responses, meaning shifts in cues in the current range may be important to the fate of trailing edge populations (Bertrand *et al.*, 2011; Lenoir & Svenning, 2015; Savage & Vellend, 2015).

Beyond the absolute level of cues, controlled environment studies need more work on what attributes of the design are more or less critical for replicating responses from the field. For example, controlled environment studies have shown differing day/night temperatures are important for some species (Heuvelink, 1989; Abrol & Ingram, 1996; Thingnaes *et al.*, 2003; Pressman *et al.*, 2006), but comparison studies have not been conducted for most species. Equally, a few studies have attempted to replicate certain aspects of the environment, such as fluctuating temperatures, ramped temperatures and the coincidence of temperature and sunrise (Erwin, 1998), but these are by no means widespread enough to understand how important these conditions are for extrapolation to models.

Understanding the physiology of phenology

Even with all the suggested above improvements, controlled environment studies will still be fundamentally limited in their utility for prediction without an improved understanding of how major phenological cues act physiologically (Bahuguna & Jagadish, 2015). This problem is most apparent with chilling, but translates also to forcing—as the two are both defined by physiological phases of dormancy that are not easily measured (Singh *et al.*, 2019; Chang *et al.*, 2021).

Chilling is defined as what leads to break of the first phase of dormancy (endodormancy), after which plants enter ecodormancy, when accumulated forcing then leads to budburst (Chuine *et al.*, 2016). Measuring endodormancy and its transition into ecodormancy, however, is notoriously difficult. Thus, in practice, most phenology studies use the terms ‘chilling’ and ‘forcing’

to mean ‘cool temperatures’ (either in the fall and winter or applied in experimental conditions) and ‘warm temperatures’ (either in the spring or applied after sufficient chilling) and generally hope they correspond to endo- and eco-dormancy—without any evidence or tests of this hoped-for correspondence. Some studies use the sequential transfer of cuttings to warm conditions to estimate the transition from endo- to eco-dormancy, with rapid and full budburst (e.g., >90% of buds on a cutting) generally meaning a plant is ecodormant (e.g., Junttila & Hänninen, 2012), but, given that this is labor- and space-intensive, few studies of chilling include this.

Physiologists have long recognized this issue and recent breakthroughs provide new insights into what causes dormancy at the cellular level (van der Schoot *et al.*, 2014). Research suggests endodormancy may break when enzymes sufficiently remove the sugar (callose) that blocks plasmodesmata in bud cells (reviewed in Chang *et al.*, 2021), but work thus far has relied generally on cellular staining methods tested on a very limited subset of species (Rinne *et al.*, 2011; Singh *et al.*, 2019), making extrapolation to other species difficult. Such results, however, hold promise for a much improved physiological understanding of endodormancy release in the future.

An improved physiological understanding of endodormancy release could revolutionize models of chilling, and in turn, estimates of forcing. Forcing in controlled environment experiments is generally defined simply as warm temperatures (or warm temperatures after cool temperatures). Future estimates could be accurately defined simply as temperatures during ecodormancy, assuming tractable tests of endo- and eco-dormancy and the uptake of such tests in controlled environment studies. With these experiment studies in hand though, researchers could quickly build improved models of chilling, and forcing and—for the first time—provide accurate predictions of how chilling will shift with climate change.

Improving integration of controlled environment and physiological studies with long-term data

Integrating long-term observational, physiological and controlled environment studies would help advance our understanding and climate change forecasting. With important exceptions (e.g., Gauzere *et al.*, 2017), studies of long-term observational phenology data have moved forward independently from advances in our physiological understanding and from controlled environment studies. Similarly, controlled environment studies, as we have reviewed here, generally do not use long-term data to help interpret results or define treatments.

Studies that have integrated results from both controlled environment experiments and with long-term observations provide a path forward that can happen now (Caffarra *et al.*, 2011; Nagano *et al.*, 2012; Satake *et al.*, 2013; Ford *et al.*, 2016; Chuine & Regnier, 2017), while we await physiological breakthroughs in defining endo- and eco-dormancy. Experiments that test for thresholds and the presence of important interactions have helped re-design models (Caffarra *et al.*, 2011; Chuine & Regnier, 2017), while other studies have used experiments to test extremes (e.g., extremely low chilling) combined with data from long-term provenance studies to understand how growth and phenology will combine to determine future ranges (Ford *et al.*, 2016). Further, some work has used controlled environments to test model predictions, especially in future climate scenarios where non-linearities are predicted (see Nagano *et al.*, 2012).

Such research underlies progress towards model development that relies continuously on a back-and-forth process between developing models based on both long-term data and experiments, then testing predictions with new experiments and newly-available observational data (i.e., more years and also data from new locations, Nagano *et al.*, 2012; Satake *et al.*, 2013). Such continual development takes extensive data and thus has been carried out on very few species (e.g., *Arabidopsis thaliana*, *Oryza sativa* (rice), *Arabidopsis halleri*, Wilczek *et al.*, 2009; Nagano *et al.*, 2012; Satake *et al.*, 2013).

Building species-rich predictions

Given the efforts and data involved in models for a single species, building up to multi-species predictions may appear daunting, but multi-species models are crucial for accurate forecasts that can apply to diverse regions and large-scale vegetation models. Addressing this issue requires, of course, more data. Long-term data is generally more species-rich than controlled environment studies. For example long-term observational data in the PEP725 and NECTAR databases together have multi-site data on more than 2500 species (Wolkovich *et al.*, 2012b; Templ *et al.*, 2018), while our review of controlled environment studies found most studies focused on only one species with data on a total of 226 species. Thus, more diverse controlled environment studies may be the current major data limitation. Beyond data, however, new modeling approaches can help integrate current and future data more powerfully.

Bayesian hierarchical models are specifically designed for analysis of diverse datasets. With the right information and sufficient data, they can attribute variation across studies to the species studied, the cues (i.e., chilling, forcing and photoperiod levels in studies) and remaining unmeasured variation in studies (i.e., differences in chamber design may be captured by including a parameter to estimate a ‘study’ effect). Such models are extremely powerful for building species-rich predictions as they leverage data across all species into one model designed to capture both the cross-species and cross-study overall effects as well as species-level differences. Yet, like all models, they are more robust with more data. In particular, attributing variation due to study versus species requires the same species to be studied across several studies, which is currently not the case for most species, according to our literature review (81% of the 226 species in our dataset appear in only one study; 32 species, or 14%, appear in two or three studies, and only 10 species, or 4%, appear in more than three studies). Thus, these models will be most useful given greater efforts to publish data. Given proper data reporting (i.e., all cue conditions defined, even when not manipulated, and controlled environment conditions should be fully described, including relative humidity and irradiance) all studies—whether designed to improve models or forecasting, or not—can be included in such models.

1.5 Right now: It’s your tomorrow

Research on phenology had been conducted for centuries before anthropogenic climate change caused earlier budburst and leafout across much of the globe (Lamb, 1948; Sparks & Carey, 1995). Decades of controlled environment studies contributed to our fundamental understanding of the drivers of spring plant phenology. Today, climate change requires leveraging these decades and centuries of research for more accurate predictions that can help humans adapt to

warming.

We have outlined how researchers could better harness the power of controlled environment experiments to transform our fundamental understanding of phenology and advance forecasting. Controlled environment studies can critically rule out, or support, hypotheses to explain observed discrepancies in long-term data and open up new pathways to use long-term data to understand current trends, helping the field move beyond trying to tease out cues using only long-term data where cues are inherently correlated. While understanding, modeling and predicting interactions among cues and their effects on phenology is challenging, it will yield more accurate predictions—with valuable implications to more realistically assess the effects of climate change on plant biodiversity, including agricultural and forest species.

3 Figures

Figure 1: Interactions can produce nonlinearities, even in simple linear models if there are correlated shifts in cues. Much research focuses on how warming increases forcing (A), but it may also alter other cues (B), including photoperiod experienced near the time of the event, which is expected to shorten, and chilling, which may either increase or decrease. Shifts in forcing alongside shifts in a second cue (A) produce non-linearities due to the interaction between cues (C-F showing the effect of: forcing-only in yellow, both cues without an interaction in light blue, and both cues with an interaction in darker blue), with the overall change in budburst day predicted with warming dependent on the sign (+/-), strength (weak and strong), and shape of the second cue (showing two simple examples: linear in C-D and threshold E-F).

Figure 2: A common example of how the level of one cue can modify another comes from experiments finding that the amount of chilling affects the amount of forcing needed for budburst. Here, we show this from Cronjé *et al.* (2003) which studied apple (*Malus sylvestris*), Sønsteby & Heide (2014) which studied black currant (*Ribes nigrum*) and Thielges & Beck (1976) which studied eastern cottonwood (*Populus deltoides*).

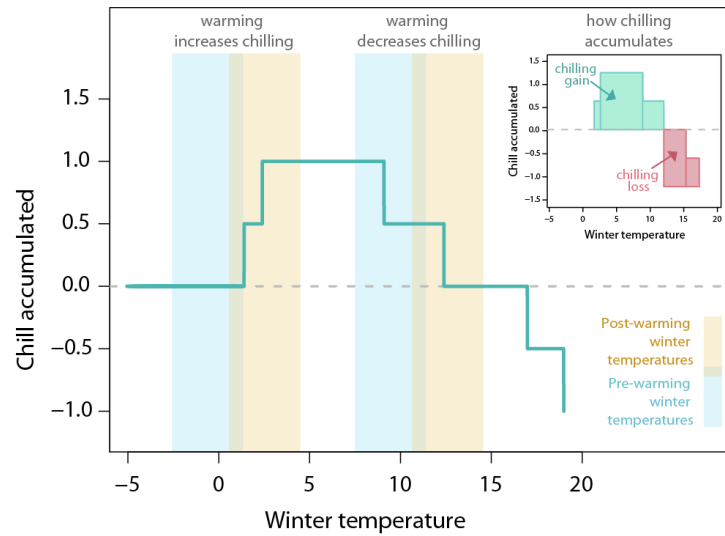

Figure 3: Current models of chilling suggest it may decrease or increase with winter warming. Here we show a common version of the Utah chilling model (top right inset and also turquoise line in main figure) with two conceptual scenarios of mean daily winter temperatures. When temperatures are generally below zero warming may increase accumulated chilling (left), while if pre-climate change temperatures are generally higher (near where chilling accumulates most per $^{\circ}\text{C}$) then warming may decrease accumulated chilling (right).

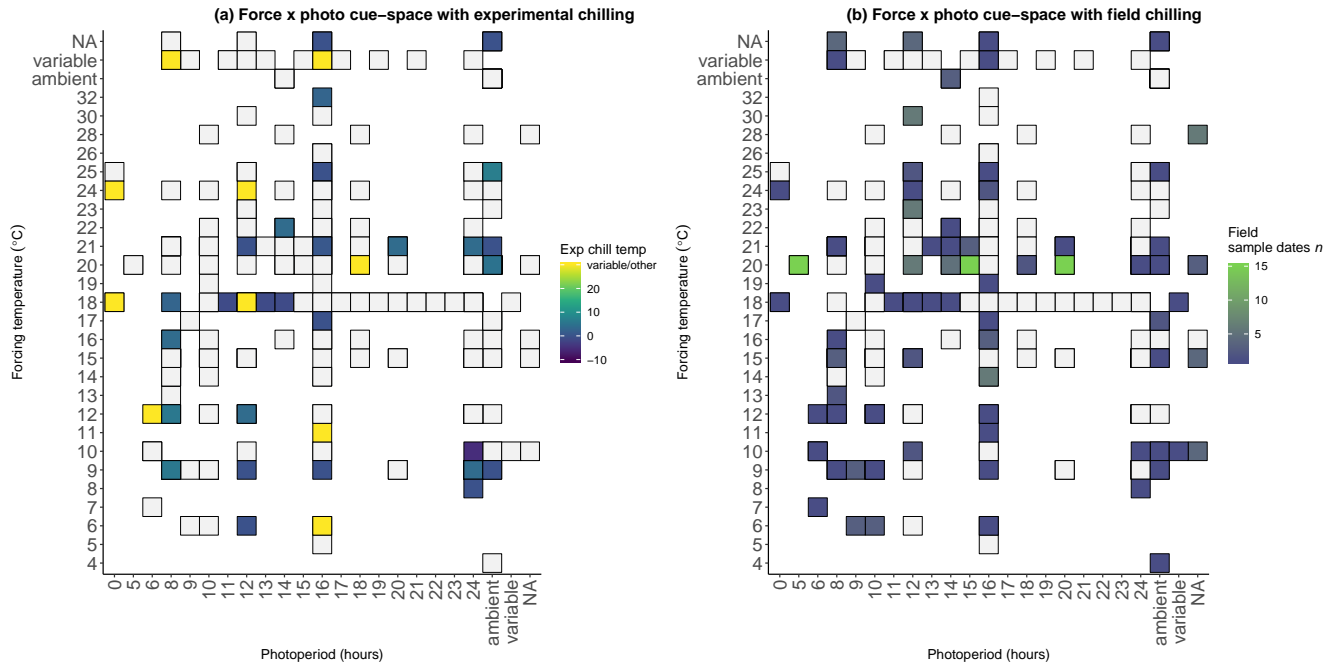

Figure 4: Studies have manipulated a range of forcing temperatures (vertical axis) and photoperiods (horizontal axis) across two methods to manipulate chilling: a) experimentally or b) using multiple field sampling dates. Gray squares indicate a combination of forcing x photoperiod not present for that method of chilling design, while a value of 'NA' indicates that we could not estimate a level of a particular cue because it was not clearly reported.

Figure 5: Comparing predicted changes in temperatures relevant to chilling (A, C) and forcing (B, D) with controlled environment studies for two species: *Fagus sylvatica* (A-B) and *Betula pendula*. Points represent a site with spring phenology data for each species respectively (from the PEP725 database, Templ *et al.*, 2018) and show the predicted change (2080s average - 1970s average) in minimum winter temperatures (A,C) and maximum spring temperatures (B,D). Inlay plots in the upper-left corner of each plot show a histogram of these same predicted changes in temperature overlaid with densities of the chilling (A, C) and forcing (B, D) differences in treatments across 33 studies (green lines show the treatments for that exact species, while black lines show across all species; for *Fagus sylvatica* there are no chilling treatments of differing temperatures). Treatment differences were calculated as the differences within varying forcing and chilling treatments within a single study (e.g., a study with a 1 and 4°C chilling treatment would yield a value of 3°C).
